★ What properties do high-likelihood sequences have that low-probability ones don’t?

High-likelihood sequences are short (5 to 31 tokens) and use simple, common words in predictable news phrasing, such as "Here is a typical case." and "All the wounded were taken to hospital." Low-likelihood sequences are long (36 to 150 tokens) and contain many hard-to-predict tokens: rare names and acronyms (NAACP, ACLU, "Kansas City Star"), numbers and dates ("9,700 petitions", "August 28th, 2017") and legal citations ("Federal Law No. 189-FZ"). Total NLL is largely a measure of length, because every token adds a positive cost. Russian sentences are overrepresented among the least likely (12 of 20) because the same content takes more tokens in Russian.

★ How does normalizing by sequence length influence this?

Normalizing removes the length effect, and the ranking separates by language: all 20 lowest per-token NLLs are Russian, and 19 of the 20 highest are English. Long Russian sentences benefit most, because Qwen splits Russian words into several subword pieces, and once a word has started, its remaining pieces are easy to predict. Short sentences move toward the worst end instead, since conditioning on only the first token leaves their early tokens hard to predict. "The problem was systemic throughout the entire country." has the highest NLL per token (5.11). Per-token NLL corrects for length but adds a tokenization bias, so it can't be compared fairly across languages that tokenize differently.

1.2

★ Why might temperature result in the observed differences?
As temperature rises, the vocabulary spreads out sharply, from 27 distinct tokens at T=0 to 962 at T=0.7, 1,841 at T=1.0 and 3,529 at T=1.2. Dividing the logits by T before the softmax makes the distribution more peaked when $T < 1$ and flatter when $T > 1$. At T=0 sampling becomes greedy, so all 50 samples are the same repetitive loop, made of a few tokens like print. At T=0.7 and T=1.0, more probability goes to less likely tokens, so the text becomes more varied and moves from code to ordinary English. At T=1.2, the tail of the distribution gets so much probability that output becomes incoherent.

★ Why might ϵ result in the observed differences?

Raising ε steadily shrinks the vocabulary, from 1,997 distinct tokens at ε=0 to 942 at ε=0.05 and 503 at ε=0.1. ε-sampling drops every token whose probability is below ε and renormalizes over what's left, so the low-probability tail is never sampled. With ε=0 nothing is filtered and the samples are ordinary T=1 samples: varied, spread-out text across many topics. At ε=0.05 and ε=0.1, generation is limited to the model's few most confident choices at each step, so it keeps falling back to the most likely continuation, a Python "hello" string example. As a result, print, (h and ello dominate the counts, and repetition increases. ε trades diversity for coherence like lowering the temperature does, but it removes the tail entirely instead of just shrinking its probabilities.

★ Why might k result in the observed differences?
Top-k sampling keeps only the k most likely tokens at each step and renormalizes over them, so k caps how many different tokens can be picked. With k=1, only the single most likely token is ever chosen, which is greedy decoding. The output matches T=0 exactly. Raising k to 20 brings in real variety, with 1,350 distinct tokens and text that switches between code, English and Chinese. Going from 20 to 100 adds comparatively little, giving 1,595 distinct tokens, still fewer than unfiltered T=1 sampling at about 1,850 to 2,000. That's because most of the probability usually sits in the top 20 tokens, so the extra 80 are rarely sampled. Unlike ε or top-p, k is fixed no matter how confident the model is. It can cut off reasonable options when the distribution is flat, and it can let in unlikely ones when the distribution is peaked.

★ Why might p result in the observed differences?
Top-p sampling keeps the smallest set of top tokens whose combined probability reaches p, then renormalizes. A larger p therefore keeps more of the tail, and the vocabulary grows: 994 distinct tokens at p=0.5, 1,528 at p=0.9 and 1,864 at p=1.0. At p=1.0 nothing is filtered, so it's the same as plain T=1 sampling. With the same random seed, it even produces the same first sample as the T=1 run. At p=0.5, the model sticks to its most confident continuations, so the "hello" Python examples (print, (h, ello) dominate the counts. Larger p allows more varied English and Chinese text. Unlike top-k, the number of kept tokens changes from step to step: it's small when the model is confident and large when it's unsure. Lengths barely change, with a mean of 85 to 90 tokens before the first EOS for every p. Every sample is exactly 100 tokens by design, and p mainly affects which tokens are chosen, not when an EOS appears.

trigram Kneser-Ney backoff validation perplexity: 620.477474319148

2.4

Neural trigram validation perplexity: 541.04

2.5

LSTM validation perplexity: 318.38

3.1

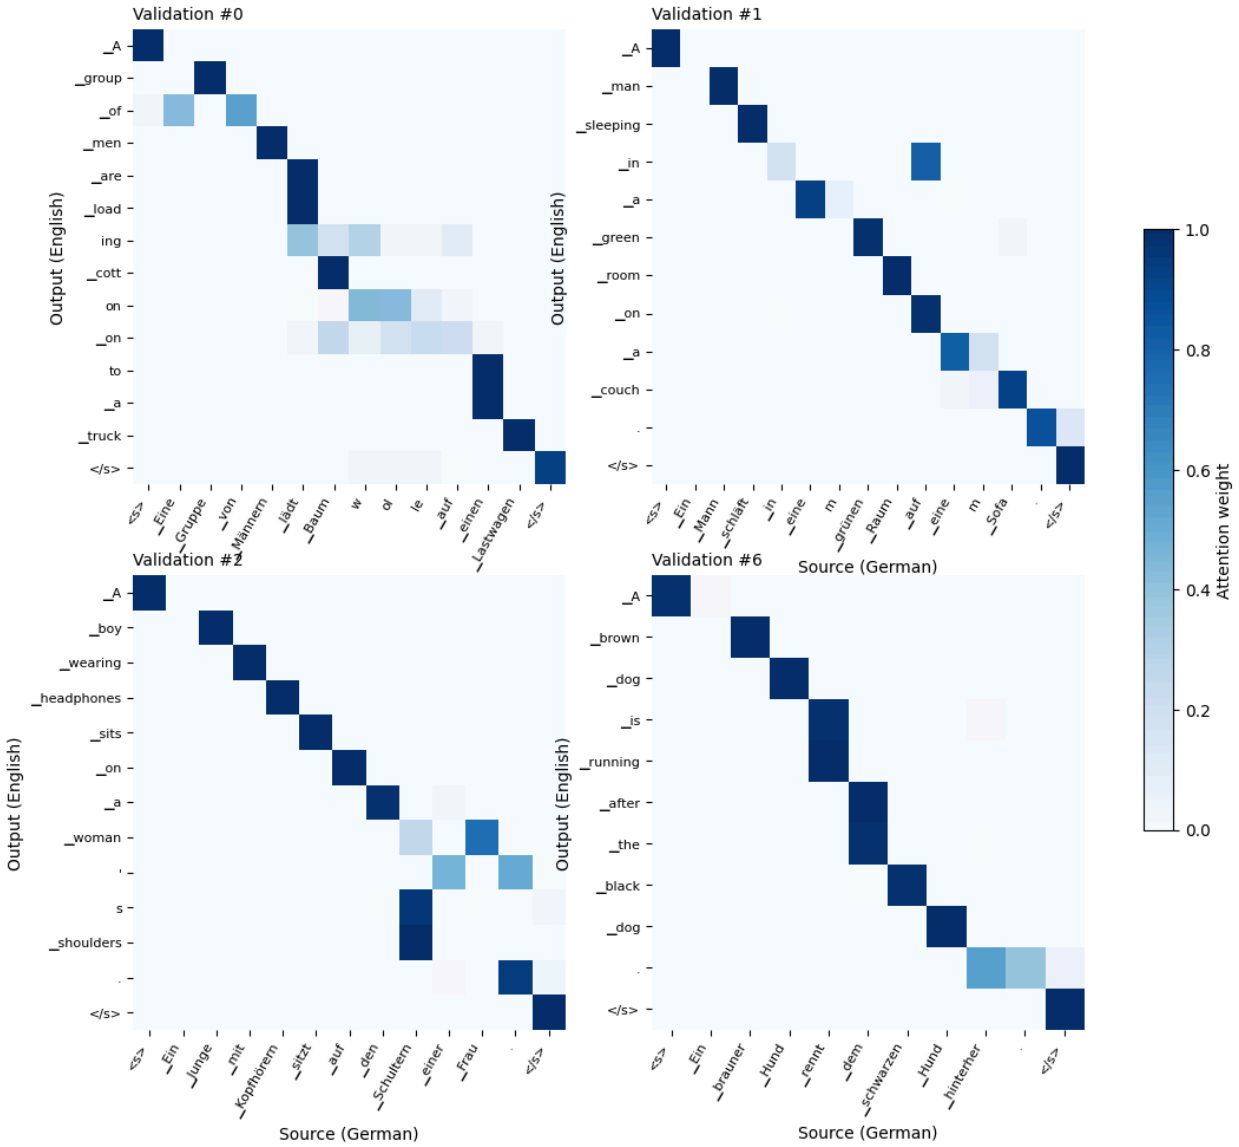

★ Report the performance of each method using accuracy, precision, recall, and F1 score. Which method performs the best? Which performs the worst? Why?

mean: acc 0.6927 P 0.6919 R 0.6948 F1 0.6933
last: acc 0.6133 P 0.6005 R 0.6771 F1 0.6365

The mean-embedding classifier performs best on every metric, and the last-token classifier performs worst. Averaging the LSTM's final-layer outputs over every token collects sentiment cues from the whole review, such as "boring" in one sentence and "brilliant" in another. A single hidden state at the last token mostly reflects the last few words. The LSTM was trained to predict the next word, not to carry a review-level judgment across hundreds of tokens, so earlier sentiment fades from its state. Reviews are also cut off at 256 words, so for long reviews the "last" token is somewhere in the middle, not the concluding verdict.

4.2

★ A figure with attention map plots for 4 sentence pairs from the validation set. We encourage you to look through more maps to aid your analysis, but please only include 4 representative plots in the figure.

★ A brief discussion over trends you discover in the plots. Do the maps line up with your intuition, are there any surprising alignments? Are there any many-to-one or many-to-many alignments, or mainly one-to-one? Using a tool like Google Translate on substrings may help give some insight into this.

Most of the attention lies close to a diagonal, and most alignments are one-to-one, as I expect. Nouns and adjectives line up cleanly with their translations: Mann→man, grünen→green, Raum→room, etc. However, many-to-one and many-to-many alignments appear when words are split differently, such as "are loading" aligning with "lädt" and "cotton" with "Baumwolle." Some word reordering also creates crossing alignments, such as "a woman's shoulders."

Surprisingly, some words attend to context rather than their direct translations. For example, "after" attends to "dem" instead of "hinterher." Overall, attention generally reflects word alignment but does not always correspond directly to translations.
